β-Lactam Monotherapy vs β-Lactam-Macrolide Combination Treatment in Moderately Severe Community-Acquired Pneumonia
A Randomized Noninferiority Trial

IMPORANCE The clinical benefit of adding a macrolide to a β-lactam for empirical treatment of moderately severe community-acquired pneumonia remains controversial.

OBJECTIVE To test noninferiority of a β-lactam alone compared with a β-lactam and macrolide combination in moderately severe community-acquired pneumonia.

DESIGN, SETTING, AND PARTICIPANTS Open-label, multicenter, noninferiority, randomized trial conducted from January 13, 2009, through January 31, 2013, in 580 immunocompetent adult patients hospitalized in 6 acute care hospitals in Switzerland for moderately severe community-acquired pneumonia. Follow-up extended to 90 days. Outcome assessors were masked to treatment allocation.

INTERVENTIONS Patients were treated with a β-lactam and a macrolide (combination arm) or with a β-lactam alone (monotherapy arm). Legionella pneumophila infection was systematically searched and treated by addition of a macrolide to the monotherapy arm.

MAIN OUTCOMES AND MEASURES Proportion of patients not reaching clinical stability (heart rate <100/min, systolic blood pressure >90 mm Hg, temperature <38.0°C, respiratory rate <24/min, and oxygen saturation >90% on room air) at day 7.

RESULTS After 7 days of treatment, 120 of 291 patients (41.2%) in the monotherapy arm vs 97 of 289 (33.6%) in the combination arm had not reached clinical stability (7.6% difference, P = .07). The upper limit of the 1-sided 90% CI was 13.0%, exceeding the predefined noninferiority boundary of 8%. Patients infected with atypical pathogens (hazard ratio [HR], 0.33; 95% CI, 0.13-0.85) or with Pneumonia Severity Index (PSI) category IV pneumonia (HR, 0.81; 95% CI, 0.59-1.10) were less likely to reach clinical stability with monotherapy, whereas patients not infected with atypical pathogens (HR, 0.99; 95% CI, 0.80-1.22) or with PSI category I to III pneumonia (HR, 1.06; 95% CI, 0.82-1.36) had equivalent outcomes in the 2 arms. There were more 30-day readmissions in the monotherapy arm (7.9% vs 3.1%, P = .01). Mortality, intensive care unit admission, complications, length of stay, and recurrence of pneumonia within 90 days did not differ between the 2 arms.

CONCLUSIONS AND RELEVANCE We did not find noninferiority of β-lactam monotherapy in patients hospitalized for moderately severe community-acquired pneumonia. Patients infected with atypical pathogens or with PSI category IV pneumonia had delayed clinical stability with monotherapy.

TRIAL REGISTRATION clinicaltrials.gov Identifier: NCT00818610

Published online October 6, 2014.
COMMUNITY-ACQUIRED PNEUMONIA ACCOUNTS FOR A HIGH BURDEN OF DEATHS, HOSPITALIZATIONS, AND HEALTH-CARE COSTS.\(^1\) OPTIMAL COVERAGE OF *STREPTOCoccus PNEUMONIAE*, GENERALLY WITH A β-LACTAM, IS ADVOCATED FOR HOSPITALIZED PATIENTS. HOWEVER, THE NEED TO COVER ATYPICAL PATHOGENS (EG, *LEGIONELLA* SPECIES, *Mycoplasma Pneumoniae*, AND *CHLAMYDIA PNEUMONIAE*) BY ADDING A MACROLIDE TO THE β-LACTAM REGIMEN OR WITH FLUOROQUINOLONE MONOTHERAPY IS DEBATED. A META-ANALYSIS\(^2\) FOUND BETTER OUTCOMES IN PATIENTS TREATED WITH THE COMBINATION OF A MACROLIDE WITH A β-LACTAM COMPARED WITH A β-LACTAM ALONE. HOWEVER, CONFOUNDING CAN BE A PROBLEM BECAUSE PATIENTS TREATED WITH COMBINATION THERAPY ARE YOUNGER AND HEALTHIER.\(^3,4\) A META-ANALYSIS\(^5\) OF RANDOMIZED TRIALS THAT COMPARED ANTIBIOTIC REGIMENS WITH AND WITHOUT COVERAGE OF ATYPICAL PATHOGENS DID NOT FIND SUPERIORITY IN EITHER ARM. HOWEVER, NO TRIAL THAT COMPARED A β-LACTAM ALONE WITH A β-LACTAM AND A MACROLIDE WAS IDENTIFIED. MOREOVER, CLINICAL SUCCESS WAS ASSESSED AFTER COMPLETION OF THE ANTIBIOTIC TREATMENT, WHICH MIGHT PRECLUDE THE IDENTIFICATION OF A DIFFERENCE IN THE SPEED OF RESOLUTION OF THE PNEUMONIA BETWEEN ARMS.

BECAUSE OF THIS UNCERTAINTY, INTERNATIONAL MEDICAL SOCIETIES DIFFER IN THEIR RECOMMENDATIONS. NORTH AMERICAN GUIDELINES RECOMMEND EMPICRICAL COVERAGE OF ATYPICAL PATHOGENS WITH A RESPIRATORY FLUOROQUINOLONE OR WITH THE COMBINATION OF A MACROLIDE AND A β-LACTAM FOR ALL HOSPITALIZED PATIENTS.\(^6\) EUROPEAN GUIDELINES RECOMMEND COMBINATION THERAPY ONLY FOR MORE SEVERELY ILL PATIENTS.\(^7\)

THE ADDITION OF A MACROLIDE HAS POTENTIAL DRAWBACKS. MACROLIDE USE IS ASSOCIATED WITH POSSIBLE ADVERSE CARDIOVASCULAR EVENTS\(^8\) AND CARDIOVASCULAR DEATH.\(^9,10\) THIS ASSOCIATION IS RELEVANT BECAUSE PNEUMONIA AFFECTS PREDOMINANTLY OLDER PEOPLE, WHO ARE AT INCREASED RISK OF HEART DISEASE, AND PNEUMONIA ITSELF IS A TRIGGER FOR ADVERSE CARDIAC EVENTS.\(^11\) MACROLIDES MAY ALSO PROMOTE RESISTANCE OF *S PNEUMONIAE* AGAINST MULTIPLE ANTIBIOTIC CLASSES.\(^12,13\) ON THE OTHER HAND, MACROLIDES COVER ATYPICAL PATHOGENS AND MIGHT AFFECT FAVORABLY THE HOST INFLAMMATORY RESPONSE THROUGH NONANTIBIOTIC EFFECTS.\(^14\) CONSEQUENTLY, POTENTIAL ADVANTAGES OF COMBINATION THERAPY SHOULD BE BALANCED WITH A POTENTIAL INCREASED RISK OF ADVERSE CARDIAC EVENTS AND INCREASED SELECTION OF RESISTANT PATHOGENS. WE AIMED TO EVALUATE WHETHER INITIAL EMPIRICAL TREATMENT WITH β-LACTAM MONOTHERAPY WAS NONINFERIOR TO THE COMBINATION OF A β-LACTAM AND A MACROLIDE IN ADULT PATIENTS HOSPITALIZED FOR MODERATELY SEVERE COMMUNITY-ACQUIRED PNEUMONIA.

**METHODS**

**DESIGN AND PATIENTS**

THE ETHICS COMMITTEES OF ALL PARTICIPATING HOSPITALS AND SWISSMÉDIC, THE SWISS REGULATORY AGENCY FOR THERAPEUTIC PRODUCTS, APPROVED THE STUDY PROTOCOL. ALL PATIENTS PROVIDED WRITTEN INFORMED CONSENT. THE BICAP DSMB, AN INDEPENDENT DATA SAFETY MONITORING BOARD, WAS INFORMED ABOUT THE NUMBER OF SEVERE EVENTS IN BOTH TREATMENT ARMS AND COULD STOP THE TRIAL IF JUDGED NECESSARY.
sequent pneumonia confirmed by chest radiography had occurred. Two investigators (N.G. and S.C.) examined separately the medical records of patients readmitted and determined the cause of readmission. Adverse events, including suspected allergy or toxic effects attributed to the antibiotic treatment, were identified on standard forms.

**Diagnostic Tests and Diagnostic Criteria**

Two pairs of blood cultures were obtained before administration of antibiotics. A urine sample was collected for detection of the *L pneumophila* antigen. Detection of the *S pneumoniae* antigen in the urine was left to the discretion of the health care professionals. Sputum and pleural fluid were sampled and cultured according to published recommendations. A pharyngeal swab was obtained on the first day of the study and processed for detection of *C pneumoniae* and *M pneumoniae* by polymerase chain reaction. Results of the swab test were not made available to the health care professionals. Diagnostic criteria are available in the eMethods in the Supplement.

**Statistical Analysis**

Because there is no randomized clinical trial, to our knowledge, that compares antibiotic treatment with a placebo in community-acquired pneumonia, we could not compute the non-inferiority margin as a percentage of the effect of the reference treatment over placebo, as generally recommended. We chose the noninferiority margin in reference to unofficial US Food and Drug Administration recommendations for antibiotic trials that assessed clinical success of a new treatment, which recommend a noninferiority margin of 10%. To be conservative, we computed the sample size with an 8% non-inferiority margin.

We assumed a proportion of patients not having reached clinical stability at day 7 of 16% in the combination arm. Continuous variables are reported as mean (SD) or median (interquartile range [IQR]) and categorical variables as number (percentage). Between-group differences were assessed using the *t* test, Wilcoxon rank sum test, *χ*² test, or Fisher exact test, as appropriate.

The proportions (SEs) of unstable patients at 7 days were measured by the Kaplan-Meier method. Unstable patients who were discharged were censored, and patients who died were considered unstable. We computed the SE on the difference between proportions (seₐ), calculated as:

\[
\sqrt{\frac{1}{m} + \frac{1}{b}}
\]

where the subscripts *m* and *b* identify the monotherapy and combination therapy arms, and used this value to obtain the upper limit of a 90% CI, which was used to test the noninferiority hypothesis, and a 2-sided 95% CI, which was provided for descriptive purposes. We also tested the null hypothesis of no difference between the proportions using a *χ*² test and reported the corresponding *P* value.

Secondary analyses were prespecified. To perform a global comparison of the 2 study arms, we obtained Kaplan-Meier estimates for the time to clinical stability along with a log-rank test and computed a hazard ratio (HR) from a Cox proportional hazards model. We performed this analysis again with an adjustment for patient age and the PSI score. Three prespecified subgroup analyses were conducted, stratifying on the category of the pathogen identified (atypical or nonatypical, defined as all patients without identification of an atypical pathogen), patient age (<65 or ≥65 years), and PSI (category I vs I to III). We also performed an additional post hoc analysis, stratifying by the CURB-65 (confusion, urea, respiratory rate, blood pressure, age ≥65 years) score (≥2 vs <2). Stratified analyses were compared in a Cox proportional hazards model that included as covariates the treatment, stratification variable, and interaction between the 2 covariates.

Because the Kaplan-Meier survival curves cross during the first week, it follows that the hazards are not strictly proportional. However, we believe that the nonproportionality is not major and that the HR captures a scientifically relevant statistic (ie, the mean HR during the first 7 days). Use of a more complex model (eg, a time-dependent treatment effect with HR[t] a linear function of In[t] or a stepwise Cox proportional hazards model with a different HR for days 0-3 and days 4-7) would improve fit, but these analyses would not test the prespecified research question, “Is there a general disadvantage (in terms of time to stability during the first week) to using monotherapy in this indication?”

Significance was defined as a 2-tailed *P* < .05. All analyses were performed in the intent-to-treat populations using SPSS statistical software, version 18.0 (SPSS Inc).

**Results**

From January 13, 2009, through January 31, 2013, we included 602 patients in the study. Twenty-two patients were excluded after randomization (Figure 1), leaving a total of 580 patients (291 in the monotherapy arm and 289 in the combination arm). Patients had a median age of 76 years (range, 21-101 years), and 351 (60.5%) had 1 or more comorbidities (median, 1.0; IQR, 0-2). The mean PSI score was 84 (Table 1).

**Microbiologic Analysis Results**

No imbalance was found between the study arms in the bacteriologic investigations (eTable 1 in the Supplement). A pathogen was identified in 180 patients (31.0%), and 48 (8.3%) had bacteremia. *Streptococcus pneumoniae*, the most common pathogen, was isolated in 43 patients (14.8%) in the monotherapy arm and 45 (15.6%) in the combination arm. *Legionella pneumophila* was identified in 12 patients (4.1%) in the monotherapy arm and 4 (1.4%) in the combination arm. The result of polymerase chain reaction for *M pneumoniae* was positive in 6 patients (2.1%) in the monotherapy arm and 9 (3.1%) in the combination arm (eTable 1 in the Supplement).

**Treatment**

Twenty-six patients (4.5%) had been treated with oral antibiotics before inclusion in the trial. Patients were treated with antibiotics for a median of 10.0 days (IQR, 8.0-12.0 days) in the monotherapy arm vs 10.0 days (IQR, 7.0-11.0 days) in the combination arm.

*β-Lactam Treatment for Pneumonia*
bination arm ($P = .41$). The β-lactam agent used was amoxicillin–clavulanic acid in 224 patients (77.0%) in the monotherapy arm and 215 patients (74.4%) in the combination arm ($P = .48$). The remaining 141 patients were treated with ceftirixime.

Initial antibiotic treatment was changed in 39 patients (13.4%) in the monotherapy arm and 46 (15.9%) in the combination arm ($P = .39$). The reasons for change are listed in Table 2 in the Supplement. Median time before administration of clarithromycin was 47 hours in the patients with \textit{L pneumophila} infection in the monotherapy arm.

**Primary Outcome**

After 7 days of treatment, 120 patients (41.2%) in the monotherapy arm had not reached clinical stability compared with 97 (33.6%) in the combination arm ($P = .07$). The absolute difference was 7.6%, with an upper limit of the 90% CI of 13.0% and a 2-sided 95% CI of −0.8% to 16.0% (Table 2). Because 13.0% is above the predefined boundary of 8%, noninferiority of monotherapy could not be demonstrated. In the survival analysis, no significant difference was found between the treatment arms (HR of reaching stability, 0.93; 95% CI, 0.76–1.13), a result that did not change significantly after adjustment for age and PSI category (Table 3). On visual inspection of the Kaplan-Meier curves (Figure 2), the difference in the proportions of unstable patients peaked on day 7 and persisted until 30 days, although it was globally nonsignificant ($P = .44$ by the log-rank test). Median time to clinical stability was 5.0 days (IQR, 3.8–6.2 days) in the monotherapy arm and 4.5 days (IQR, 3.9–5.1 days) in the combination arm. Mean time to clinical stability and stabilization of the independent vital parameters is given in eTable 3 in the Supplement.

**Subgroup Analysis**

In the subgroup analysis, the effect of the treatment arm differed significantly for patients with identification of an atypical pathogen (HR of reaching stability, 0.33; 95% CI, 0.13–0.85) and those without (HR, 0.99; 95% CI, 0.80–1.22). Combination therapy was significantly superior for patients with atypical pathogens (Table 3). There was a trend toward better outcome of the combination therapy for patients with more severe pneumonia (Table 3 and eFigure 1 in the Supplement). Patients with PSI category I to III pneumonia had an HR of reaching stability of 1.06 (95% CI, 0.82–1.36) with monotherapy. The corresponding HR was 0.81 (95% CI, 0.59–1.10) for patients with PSI category IV pneumonia ($P = .18$ for trend). When stratifying on the basis of the CURB-65 score, the HR of...
reaching stability with monotherapy was 1.13 (95% CI, 0.85-1.50) for patients with CURB-65 scores of 0 or 1 and 0.80 (95% CI, 0.61-1.06) for patients with CURB-65 scores of 2 or higher (P = .09 for interaction). No interaction was found between age and treatment arm (Table 3).

In a post hoc analysis that excluded all patients with proven infection by an atypical pathogen, the proportion of patients not having reached clinical stability at day 7 was 39.9% in the monotherapy arm and 34.1% in the combination arm (absolute difference, 5.8%; 95% CI, −2.7% to 14.3%; P = .15). Mean PSI scores were 86.4 in patients with and 84.2 in patients without a proven atypical pathogen infection (P = .64 by analysis of variance).

Secondary Outcomes
No difference was found between the 2 arms in most secondary outcomes (Table 2). However, at 30 days after discharge, more patients in the monotherapy arm had been readmitted (7.9% vs 3.1% in the combination arm, P = .01). Of the 23 patients in the monotherapy arm who had been readmitted, 7 (30.4%) had a new episode of pneumonia vs 0 of 9 in the combination arm (P = .06). Other causes of readmission or proportion of patients treated for a new episode of pneumonia (in the hospital or as outpatients) did not differ between the treatment arms (Table 2 and eTable 4 in the Supplement).

There was a trend toward more severe events in the monotherapy arm in patients infected with an atypical pathogen, including 3 intensive care unit admissions (all 3 patients were infected with *L pneumophila* vs none [P = .12], respectively and 2 deaths (both patients were infected with *M pneumoniae*) at 30 days vs none (P = .21), respectively (eTable 5 in the Supplement).

Safety
Adverse events attributed to the antibiotic treatment were infrequently reported. One patient in the monotherapy arm and 2 patients in the combination arm had acute hepatitis without hepatic failure, and 1 patient in the combination arm had renal failure attributed to acute interstitial nephritis and needed

Abbreviations: CURB-65, confusion, urea, respiratory rate, blood pressure, age of 65 years or older; PSI, Pneumonia Severity Index.
<sup>f</sup> Reference category is the combination arm.
covered by β-lactam drugs. This advantage, not present in patients with atypical pathogens, better coverage of atypical pathogens is unlikely to explain this differential effect. Second, in an analysis that excluded patients with atypical pathogens, the tendency toward a better outcome in the combination arm persisted (proportion of patients not attaining clinical stability 7 days after treatment, 5.8% compared with 7.6% in the primary analysis). Third, none of the 23 patients readmitted at 30 days in the monotherapy arm had been infected by an atypical pathogen. Better control of the host inflammatory response through a nonantibiotic effect of clarithromycin might have protected patients in the combination arm from adverse events that led to readmission.

Patients enrolled in the trial are representative of patients commonly hospitalized for community-acquired pneumonia, with 25% of patients older than 84 years and a high prevalence of chronic disease. We used strict inclusion criteria. Less than 5% of patients had been treated with oral antibiotics before inclusion, maximizing the effect of the allocated therapy, and adherence to the protocol and follow-up were excellent, with only 3 patients unavailable for follow-up and 85 (14.7%) with a change in treatment allocation (Figure 1).

Discussion

We were unable to demonstrate noninferiority of initial empirical treatment with a β-lactam agent alone in hospitalized patients with moderately severe community-acquired pneumonia. There was a nonsignificant trend toward superiority of combination therapy, which could represent a chance finding or true superiority that was not significant because of insufficient power. Although most secondary outcomes did not differ between the 2 treatment arms, patients in the monotherapy arm had more readmissions within 30 days. This finding might also point toward a superiority of combination therapy.

One advantage of the combination therapy is added coverage of atypical pathogens with the macrolide. A Cochrane review included randomized clinical trials that compared treatment regimens with and without atypical coverage. The review did not find a difference in mortality (relative risk [RR], 1.14; 95% CI, 0.84-1.55), but there was a nonsignificant trend toward fewer clinical failures in the atypical arm (RR, 0.93; 95% CI, 0.84-1.04). However, macrolide treatment might also affect favorably the host inflammatory response through nonantibiotic effects. Macrolide treatment confers clinical benefits in chronic inflammatory airway conditions, such as bronchiectasis and chronic obstructive pulmonary disease, but this benefit is not established in community-acquired pneumonia. In a recent meta-analysis, macrolide use was associated with a statistically significant mortality reduction (RR, 0.78; 95% CI, 0.64-0.95), an advantage that disappeared when the analysis was restricted to randomized clinical trials (RR, 1.13; 95% CI, 0.65-1.98). A meta-analysis of 16 observational studies comparing β-lactam–macrolide combination with a single β-lactam in more than 42,000 patients with all-cause pneumonia found a lower risk of death in favor of the combination treatment (odds ratio, 0.67; 95% CI, 0.61-0.73). An advantage for combination therapy also has been reported for patients with S pneumoniae, although this pathogen is adequately covered by β-lactam drugs. This advantage, not present in all studies, fueled the hypothesis of an immunomodulatory effect of the macrolide.

In our study, combination therapy was superior in patients with proven infection by an atypical pathogen, despite systematic search for L pneumoniae infection by urinary antigen testing and subsequent addition of a macrolide in patients undergoing monotherapy. This superiority may be explained by failure to provide timely coverage of the Legionella infection. The median time between administration of the β-lactam drug and the addition of clarithromycin was 47 hours for patients with L pneumoniae infection in the monotherapy arm. This long interval reflects real-life practice, with delays in collecting a urine sample for testing, receiving the results, and prescribing the appropriate antibiotic. These delays may have had repercussions on the concerned patients because 3 of them were transferred to the intensive care unit because of clinical deterioration (eTable 5 in the Supplement). Moreover, sensitivity of the test for L pneumo-
and Table 2). The primary outcome was based on objective physiological measurements, and outcome assessment was masked. Finally, we assessed the outcome at an early time point, in accordance with published recommendations.30-31

Our trial was open, and knowledge of treatment allocation could have biased clinical decision making. However, we did not observe a difference in the adherence to the assigned treatment between the 2 arms. The study was conducted in Switzerland, and results cannot automatically be generalized to other regions where prevalence of atypical bacteria and resistance of *S pneumoniae* may differ. Specifically, *L pneumophila* causes 99% to 98% of *Legionella* pneumonias in Switzerland, most of them being diagnosed by urinary antigen testing.32

A high percentage of patients had not reached clinical stability at 7 days, and the median time to clinical stability was higher than in other trials.33,34 However, our results were comparable with those of a large international observational study.35 Several characteristics of our study can explain the longer-than-expected time to clinical stability. We took into account patients dying in the hospital and patients who never reached clinical stability during the acute care stay but were later transferred to a rehabilitation facility by censoring them at 30 days. These patients were excluded from other studies33,34 that evaluated time to clinical stability. In fact, when we repeated the analysis on the population of patients discharged to their home, we found a median time to clinical stability of 3.5 days (IQR, 3.1-3.9 days), in line with previous studies.33-34

Finally, despite randomization, a striking imbalance was found in the repartition of *Legionella* between the treatment arms, which could have favored the combination arm.

**Conclusions**

Our results have important clinical implications. First, the results of this trial indicate that initial empirical treatment with β-lactam monotherapy delays clinical stability for patients infected with atypical pathogens, even when the presence of *Legionella* is systematically searched for with urinary antigen testing. Whether faster introduction of a macrolide in patients with a positive test result would have resulted in better outcomes is hypothetical. Second, patients with higher severity of pneumonia (PSI category IV or CURB-65 score of ≥2) seem also to benefit from combination therapy. Future work might test a strategy of tailoring the initial therapy on the severity of the pneumonia, with combination therapy reserved for patients with PSI category IV or higher pneumonia or a CURB-65 score of 2 or greater.
