Anti-angiogenic therapies are currently in cancer clinical trials, but to date there are no established tests for evaluating the angiogenic status of a patient. We measured 11 circulating angiogenesis-associated molecules in cancer patients before and after local treatment. The purpose of our study was to screen for possible relationships among the different molecules and between individual molecules and tumor burden. We measured VEGF-A, PIGF, SCF, MMP-9, EDB−β3-bromerin, sVEGFR-2, sVEGFR-1, sVEGFR-2, MMP-9, sTie-2, IL-8 and CRP in the blood of 22 healthy volunteers, 17 early breast, 17 early colorectal, and 8 advanced sarcoma/melanoma cancer patients. Breast cancer patients had elevated levels of VEGF-A and sTie-2, colorectal cancer patients of sVEGFR-1, sVEGF-9, sTie-2, IL-8 and CRP, and melanoma/sarcoma patients of sVEGFR-1. sVEGFR-2 was decreased in colorectal cancer patients. A correlation between VEGF-A and MMP-9 was found. After tumor removal, MMP-9 and sVEGFR-2 significantly decreased in breast and CRP in colorectal cancer, whereas sVEGF-R-1 increased in colorectal cancer patients. In sarcoma/melanoma patients treated regionally with TNF and chemotherapy we observed a rise in VEGF-A, SCF, VEGFR-2, MMP-9, Tie-2 and CRP, and a correlation between CRP and IL-8, and a decreased in sVEGFR-1 levels. In conclusion, among all factors measured, only VEGF-A and MMP-9 consistently correlated to each other, elevated CRP levels were associated with tumor burden, whereas sVEGF-R-1 increased after tumor removal in colorectal cancer. Treatment with chemotherapy and TNF induced changes consistent with an angiogenic switch. These results warrant a prospective study to compare the effect of surgical tumor removal vs. chemotherapy on some of these markers and to evaluate their prognostic/predictive value.

Key words: surrogate markers: angiogenesis; predictive; TNF; chemotherapy

Angiogenesis promotes local tumor progression and invasion and enables tumor cell dissemination and metastasis formation. Many preclinical studies show that the inhibition of angiogenesis can suppress tumor growth and metastatic dissemination. Bevacizumab (Avastin), a neutralizing antibody specific for vascular endothelial growth factor (VEGF)-A in combination with standard chemotherapy (i.e., CPT-11, 5-FU and Leucovorin) extends survival and this combination was approved for patients with advanced colorectal cancer. This result represents a proof-of-concept for the role of angiogenesis in human cancer progression and demonstrates that VEGF-A is a valid molecular target for the management of colon cancer.

The inhibition of the formation of new vessels, or the disruption of established vessels is not easily seen using the standard response criteria of clinical oncology because these are based mainly on measurement of tumor size. The ability to monitor tumor angiogenesis in patients would greatly facilitate the clinical development of anti-angiogenic treatments. Some imaging techniques, such as angiography, contrast-enhanced dynamic nuclear magnetic resonance, computer tomography and position emission tomoscopy allow perfusion measurements at tumor sites, but they are not routinely used in the clinic as they are expensive and require sophisticated equipment and expertise. No validated biomarker currently allows the reliable monitoring of tumor angiogenesis in patients.

Several molecules implicated in angiogenesis have been identified, some detectable in the systemic circulation. VEGF-A, matrix metalloproteinase (MMP) -2 and MMP-9, soluble VEGF receptor-1 (sVEGFR-1), soluble VEGF receptor-2 (sVEGFR-2) and soluble Tie-2 (sTie-2) have been studied in a wide variety of cancers, including breast, ovary, brain, kidney, bladder, prostate, lung, gastro-intestinal cancers, hematological malignancies, hepatocarcinoma, melanoma and sarcomas. Correlations between elevated levels of some of these molecules, in particular VEGF-A and MMP, and the presence of a tumor, its stage or grade, progression and clinical outcome have been reported. In most studies, only one or a few markers were evaluated simultaneously. The possibility of improving sensitivity or specificity by the simultaneous measurement and analysis of multiple candidate markers has not yet been evaluated.

We measured in parallel 11 different angiogenesis-associated molecules in the blood of patients before and after curative-intent loco-regional treatment and of healthy volunteers. We selected these markers from previous reports of their altered levels in tissue or blood of cancer patients or because preclinical and pathological studies have indicated an association with tumor angiogenesis. Placenta growth factor (PIGF) and VEGF-A are vascular growth factors that bind to and activate VEGF-R-1 and VEGF-R-2, respectively. PIGF has been reported recently to play a role in pathological angiogenesis, but its biological and clinical relevance in cancer is unclear. Stem cell factor (SCF) promotes release of hematopoietic and vascular progenitor cells from the bone marrow. VEGF-R-1 and VEGF-R-2 are receptors for the VEGF family members, which can induce angiogenesis. Integrin αvβ3 is a cell adhesion receptor highly upregulated on angiogenic endothelial cells. Tie-2 is a receptor for the angiopoietins, which promotes endothelial cell survival and vascular remodeling. MMP-9 is a matrix-degrading enzyme upregulated in inflammation and cancer that was found to induce the angiogenic switch in preclinical cancer models. EDB−β3-bromerin (EDB−β3-Fn) is a fibronectin-spike variant absent from most normal tissues, but allows the reliable monitoring of tumor angiogenesis in patients.

Received 28 March 2005; Accepted after revision 31 May 2005 DOI 10.1002/ijc.21408 Published online 19 August 2005 in Wiley InterScience (www.interscience.wiley.com).
expressed in tumors in close association with angiogenic vessels, although the EDB domain itself is dispensable for tumor angiogenesis and tumor progression. Interleukin (IL)-8 has been associated with tumor progression and angiogenesis in several cancers, including breast, prostate, and colorectal. It was reported recently that Ras-dependent IL-8 secretion is critically involved in initiating tumor-associated inflammation and neoangiogenesis.

Elevated serum C-reactive protein (CRP) levels were reported to be associated with elevated risk of developing colorectal cancer, a more aggressive progression and unfavorable prognosis. More recently elevated CRP levels were found associated with angiogenic factors in multiple myeloma.

The aim of our study was to identify possible trends and relationships between these factors, which could subsequently be validated in prospective trials for their prognostic or predictive value. Our study was carried out on patients with localized and previously untreated breast or colorectal cancers scheduled to undergo primary curative-intent resection. We also analyzed patients undergoing local treatment by isolated limb perfusion with high dose TNF and chemotherapy for locally advanced/relapsed melanoma or sarcoma. This modality of treatment permitted us to explore the difference of angiogenic response between loco-regional surgery compared to chemotherapy.

Material and methods

Study population

Eligible patients were 18 years of age or older, presenting non-metastatic breast (BC) or colorectal cancer (CRC) and scheduled for tumor resection, and loco-regional refractory or relapsed melanoma or sarcoma scheduled for isolated limb perfusion (ILP). Exclusion criteria included patients with <10 g/dl hemoglobin, leucopenia, thrombocytopenia, deep venous thrombosis during the last 3 months, long-term vascular catheter, chronic vascular or inflammatory disease, surgery and chemotherapy during the last 4 and 6 months respectively.

ILP is a technique of locoregional treatment where tumor necrosis factor alpha (TNFα, Beromun; dose = 1-4 mg) and high dose melphalan (Alkeran; 10 mg/l of the limb volume) are perfused through an extracorporeal circulation into a limb isolated from the systemic circulation by a tourniquet. For melanoma, gamma interferon (IFNγ, Imukan; 0.2 mg) is also added in the perfusate.

Healthy volunteers were at least 18 years old, without history of cancer, chronic disease or medication other than hormonal contraception. Ethical and scientific approval were given by the local Ethics Committee. Written informed consent was obtained from all the patients and healthy volunteers.

Study design

Blood was obtained before and more than 4 weeks after treatment by peripheral venous puncture. Serum and plasma were extracted during the following 2 hr.

Plasma isolation

Blood was collected in heparin containing tubes. After 30 min centrifugation at 400g at 20°C, the plasma was extracted and frozen at −80°C.

Serum isolation

Blood was collected in tubes without anticoagulant. After 10 min centrifugation at 1,000g, the serum was extracted and frozen at −80°C.

Samples analyses

The samples were thawed just before use. All molecules were measured in serum, except for VEGF-A, MMP-9, sVEGFR1, sVEGFR-2, SCF, and TNFα. VEGF-A, SCF, sVEGFR1, sVEGFR-2, SCF, MMP-9, and TNFα were carried out using the Quantikine ELISA systems (R&D Systems, Abingdon, UK). The sVEGFR1 Quantikine ELISA does not differentiate between sVEGFR1 generated by alternative splicing and sVEGFR1 generated by proteolytic cleavage at the cell surface. IL-8 was measured using and ELISA system from Amersham Bioscience (Buckinghamshire, UK). CRP was measured using an ELISA system from Hyphen BioMed (Neuville-sur-Oise, France). EDB−Fn was measured with an ELISA by Adeza Biomedical (Sunnyvale, CA). saVβ3 was measured using an ELISA developed for our study (see below). Each data point was measured in duplicate. Optical density of each well was measured at 450 nm in a multwell plate reader (Packard Spectra Count, Meriden, CT). For practical reasons, only means are described below, as there was very little divergence between means and medians. To identify putative correlations between the levels of individual factors they were compared to each other.

Capture ELISA for soluble Vβ3

Anti-integrin αV (clone 272-17E6, Calbiochem, San Diego, CA) was adsorbed on 96-well plates (Maxisorp, Nunc, Roskilde, Denmark) from a coating solution of 2 µg/ml in PBS (1 hr at 4°C). Plates were blocked with 5% BSA in PBS. The assay was carried out in PBS containing 0.1% BSA and 0.01% Tween 20 (dilution buffer). Plasma samples were diluted and incubated on the plates for 60 min at 37°C. After washing, biotinylated anti-β3 antibody at 2 µg/ml (clone 20H9)31 was incubated on the plates for 60 min at 37°C. Plates were washed with dilution buffer, and anti-biotin peroxidase conjugate (Sigma, Deisenhofen, Germany) was added for 60 min at 37°C. Results were quantified by comparison to a reference curve produced using purified recombinant saVβ3.32

Statistical analysis

Analysis was descriptive and exploratory. Mann-Whitney U-test was used in the comparison between healthy volunteers and cancer patients. The changes in the levels of factors before and after treatment were estimated by Wilcoxon signed-rank test. Results were considered statistically significant for p ≤ 0.05.

Results

Study population

Forty-six patients were recruited, 4 patients were excluded from the analysis because of the absence of an invasive cancer (3 BC patients) or the presence of metastatic disease (1 CRC patient). Of the 42 eligible patients there were 17 female BC patients, 17 CRC patients and 8 cases of loco-regional relapsing/refractory sarcoma or melanoma (ILP patients). Patient characteristics are described in Table 1.

Breast cancer (BC). Thirteen patients with invasive cancer were treated by tumorectomy and 4 patients by mastectomy. Axillary lymph node and sentinel node dissection were carried out in 11 and 6 patients, respectively. Post-surgery blood samples were obtained at a median time of 6.9 weeks after treatment.

Colorectal cancer (CRC). Tumor localizations were in rectum (n = 2), rectosigmoid (n = 3) and colon (n = 12). Patients were treated by hemicolectomy (n = 14) and low anterior resection (n = 3). Post-surgery blood samples were obtained at a median time of 8.9 weeks after treatment.

Isolated limb perfusion (ILP) patients. Four sarcoma patients were included (1 liposarcoma Grade 2, 1 angiosarcoma Grade 3 and 2 synovial sarcomas, Grade 2 and 3). The indications for ILP in sarcoma patients were progression after first line surgery, bulky initial tumors and first local relapse. No lymph node or distant metastases were present before ILP. Melanoma patients were treated by ILP for in transit metastasis. Post-surgery blood sam-

Forty-two cancer patients were analyzed in this study: 17 female breast cancer patients, 17 colorectal cancer patients and 8 cases of loco-regional relapsing/refractory sarcoma or melanoma, ND, not done.

Measured concentrations of the individual factors

VEGF-A. The differences of the mean values between volunteers and cancer patients (Table II, Fig. 1a) were statistically significant for BC (p = 0.036) and CRC (p = 0.001). After surgical tumor resection a trend toward a decrease of the mean levels of VEGF-A was observed for BC and CRC. In 6 CRC patients, however, VEGF-A levels slightly increased after surgery (Table III, Fig. 1b). In ILP patients, an increase in VEGF-A concentration after therapy was observed in all patients, except one who had elevated level of VEGF-A at baseline (Table III, Fig. 1c). Of note is that this patient had in transit metastases of melanoma and subsequently developed a disseminated disease within 1 month. There was no correlation between platelets count and VEGF-A in the patients, thus excluding that we were measuring VEGF-A released from platelets.

PIGF and SCF. No significant differences were observed for PIGF and SCF between healthy volunteers and BC, CRC or patients undergoing ILP (Table II). Treatment had no significant effect on PIGF levels. SCF levels did not change after treatment in BC and CRC whereas it rose by approximately 20% in ILP patients (Table III).

sVEGFR-1. The mean values of sVEGFR-1 were only slightly higher in BC and CRC patients compared to healthy volunteers whereas it was significantly higher in ILP patients compared to controls (Table II, Figure 2a). After treatment we observed a tendency of increasing values in BC patients, a significant increase in CRC patients and a significant decrease in ILP patients (Table III, Figure 2b and 2c).

sVEGFR-2. Only minor differences in sVEGFR-2 mean values were observed between healthy volunteers and cancer patients. CRC patients had significantly lower levels of sVEGFR-2 compared to healthy volunteers, but the difference was small (13%) (Table II). No relevant modifications were observed after treatment in BC and CRC patients, whereas the sVEGFR-2 mean level rose significantly in ILP patients (Table III).

sTie-2. The mean values of sTie-2 were significantly higher in BC and CRC patients, compared to healthy volunteers, although the differences were small (Table II). After treatment no relevant changes were observed in BC and CRC patients, whereas in ILP patients sTie-2 levels rose significantly (Table III).
VEGF-A levels: (a) VEGF-A values before treatment; (b) VEGF-A values after treatment in colorectal cancer patients; (c) VEGF-A values before and after treatment in breast cancer patients. The short horizontal lines indicate mean values.

Breast and colorectal cancer patients were treated by surgery whereas melanoma and sarcoma patients were treated by isolated limb perfusion with TNFα, IFNγ and Melphalan. Bold typing denotes values that are significantly different in cancer patients after therapy compared to pre-treatment values. HV, healthy volunteers; BC, breast cancer; CRC, colorectal cancer; ILP, sarcoma or melanoma. Results represent mean values ± SD. \( p \leq 0.05 \) was considered statistically significant.
sVEGFR-1. The mean values of sαVβ3 were significantly lower in CRC and ILP patients compared to healthy volunteers, whereas in BC patients sαVβ3 concentrations were comparable to healthy donors (Table II). A minor, but statistically significant decrease in sαVβ3 was observed in BC patients after therapy (Table III). In CRC and ILP patients sαVβ3 levels were not affected by the treatment. There was no correlation between the sαVβ3 level and number of circulating platelets.

MMP-9. The mean concentrations of MMP-9 were higher in all patient populations, compared to healthy donors, although the difference was statistically significant only in CRC patients (Table II, Fig. 3a). After treatment we observed a significant drop in the mean levels of MMP-9 in BC patients, a trend toward decrease concentrations in CRC patients and a trend toward increased levels in ILP patients (Table III, Fig. 3b,c).

EDB+ -Fn. The mean values of EDB+ -Fn were significantly lower in BC, CRC and ILP patients than in healthy volunteers (Table II). EDB+ -Fn levels were slightly higher after treatment than before therapy, but the modifications did not reach significance in any of the cancer types (Table III).

IL-8. The mean values of IL-8 were significantly higher in CRC patients compared to healthy volunteers (Table II). These elevated levels decreased upon tumor removal, but did not reach statistical significance (Table III).

CRP. Mean CRP levels were elevated in CRC and ILP patients, but reached statistical significance only in CRC patients (Table II, Fig. 4a). CRP levels returned within the normal range in CRC patient upon surgical tumor removal, whereas they increased significantly in ILP patients after treatment (Table III, Fig. 3b,c).

Correlation between different factors

The analyses of the results showed that subjects with higher pre-treatment levels of VEGF-A tended to have higher levels of MMP-9 and the converse. This correlation was observed in both BC and CRC patients, although it was most relevant for the latter (R² = 0.58 and R² = 0.77, respectively) (Fig. 5a and not shown). In ILP patients we also observed a strong correlation, which, however, was largely influenced by one single patient (R² = 0.95; if highest value omitted, R² = 0.55) (Fig. 5b). There was a trend for a correlation between elevated IL-8 levels and VEGF-A and MMP-9 concentrations (R² = 0.604 and R² = 0.402, respectively, data not shown). Similarly CRP and MMP-9 levels and CRP and VEGF-A levels tended to correlate (R² = 0.43 and R² = 0.36, respectively), although to a lesser extent. There was a correlation between post-treatment levels of IL-8 and CRP in ILP patients (R² = 0.69) (Fig. 5c). No other relevant positive or negative correlations were observed between any of the other factors.

Correlation with clinical parameters

Given the small number of patients these correlations are only indicative of trends based on median values.

VEGF-A. In BC we observed a trend between increased VEGF-A levels and advanced tumor stage (Stage I < Stage II < Stage III), size (T1 < T2), grade (G1 < G2 < G3), absence of estrogen receptor expression (negative > positive) and lymph node invasion (negative < positive). In colorectal cancer, VEGF-A levels were higher in patients with larger tumors, higher tumor stages (Stage I < Stage II–III), tumor infiltration (T1 < T2 < T3) and lymph node invasion (N1 < N2).

sVEGFR-1. In BC patients lower sVEGFR-1 levels were associated with higher stages (Stage I > Stage II > Stage III), larger tumors (T1 > T2) and lymph node infiltration (negative > positive). In CRC patients, however, the trend was the opposite: sVEGFR-1 levels were higher for higher stages (Stage I < Stage II–III), tumor infiltration (T1 < T2–T3) and lymph node invasion (N1 < N2).

MMP-9. In BC, MMP-9 levels were higher in higher stages (Stage I < Stage II < Stage III) and higher tumor size (T1 < T2).
In CRC, higher MMP-9 correlated with the stage (Stage I < Stages II–III) tumor infiltration (T1 < T2 < T3) and lymph node invasion (N1 < N2).

Discussion

Our work was initiated as an exploratory study aimed at measuring multiple angiogenesis-associated molecules in the blood of cancer patients, analyzing putative correlations and identifying molecules as candidate markers for further investigation in prospective clinical studies. Each factor was measured within the same patient before and after resection of the primary tumor (BC and CRC). The measurements were also carried out in a small group of patients undergoing curative-intent regional chemotherapy with TNF for loco-regionally advanced sarcoma or melanoma of the limb, and in healthy individuals.

In breast and colorectal cancer patients, only few of the tested factors were altered significantly compared to healthy volunteers. There was an important inter-patient variation leading to extensive overlap with the healthy subjects. If the level of a given factor was directly related to the presence of the tumor, one would expect altered levels for it in a majority of the patients. This simple expectation was not confirmed. SCF, PIGF and sVEGFR-1 were not increased in patients with tumors, whereas VEGF-A, sVEGFR-2, sTie-2, saVß3, EDB−Fn and MMP-9 showed some significant differences compared to healthy donors, but with an important heterogeneity within patients. In breast and colorectal cancer patients, VEGF-A and MMP-9 were the 2 markers that best fulfilled the characteristics expected for surrogate marker of angiogenesis: they were elevated in patients before treatment (although only in about a third of the breast cancers and a half of the colorectal cancers), and their values dropped after tumor removal. Fourteen colorectal cancer patients and one breast cancer patient responded to tumor removal by a clear increase in sVEGFR-1 levels (Fig. 2c). The reason for this change is not clear. VEGFR-1 is produced in 2 isoforms with contrasting functions in angiogenesis. The full-length transmembrane form stimulates angiogenesis by transactivating VEGFR-2,14 promoting the release of hematopoietic and angiogenic precursor cells from bone marrow,15 stimulating the migration of monocytes16 and activating lung endothelial cells at premetastatic sites.17 In contrast, the soluble form (sVEGFR-1), which consists of the extracellular domain as a result of alternative mRNA splicing,16 binds and inactivates circulating VEGF-A18 and is considered to be an endogenous negative regulator of angiogenesis. In breast cancer, a low VEGFR-1/VEGFR-A ratio in the tumor tissue itself was reported to be a poor prognostic factor.19 One could hypothesize that in our patients, the tumor itself may inhibit sVEGFR-1 production, and that this inhibition is abrogated upon tumor removal. The implication of the increase in sVEGFR-1 observed in some of the operated patients is unknown at this point. It should also be stressed that sVEGFR-1 can also be generated by proteolytic cleavage of the transmembrane form at the cell surface. The assay used in our study does not allow to differentiate between the 2 forms. It is therefore possible that the sVEGFR-1 measured in these patients may consist of a mixture of the alternatively spliced variant, and of the proteolytically cleaved form. Because these 2 forms may reflect different biological events or cellular sources, it may be worth to address this question in future studies. Compared to healthy volunteers, sVEGFR-2 and sTie-2 were slightly but significantly increased (approximately 15–50 % of normal values). In contrast, the mean values of saVß3 and EDB−Fn were several folds lower in cancer patients vs. healthy volunteers. The absence of correlation between the number of circulating platelets and the level of saVß3 suggests that platelets are unlikely to be the source of the saVß3 measured here. Although on a per platelet basis, αVß3 is much less abundant than aibß3 (about 1,000 vs. 50,000 copies),20 platelet-derived αVß3 could be of potential concern considering the large number of circulating platelets. The biological significance of these molecules as surrogate markers of angiogenesis is questionable because their levels did not change after tumor removal. This

Figure 3 – MMP-9 levels (a) MMP-9 values before treatment. Colorectal cancer patients had significantly higher levels compared to healthy volunteers. (b) Values before and after treatment in breast cancer patients. (c) Values before and after treatment in colorectal cancer patients. HV, healthy volunteers; BC, breast cancer; CRC, colorectal cancer; ILP, sarcoma and melanoma patients. The short horizontal lines indicate mean values.
observation, however, raises the intriguing questions of whether these patients may have constitutively altered levels of these molecules and whether altered levels may correlate with an enhanced angiogenic response or susceptibility to tumor progression ('predisposition factors'). This hypothesis may be of particular relevance for αVF3, because mice lacking αVF3 expression were reported to have enhanced tumor angiogenesis and tumor growth.39

CRP behaved as a tumor marker for colorectal cancer patients: it was significantly elevated before treatment and it returned within normal levels after surgery. The trend toward a positive association with VEGF-A and MMP-9 levels, although not as strong and between VEGF-A and MMP-9, hints at a possible association with angiogenesis. Apparently contrasting observations about a possible role of CRP in controlling angiogenesis exist in the literature. In multiple myeloma CRP positively correlated with blood levels of VEGF, and with increased bone marrow angiogenesis.40,41 Elevated levels of CRP were reported associated with a reduced number of circulating endothelial cell precursors in cardiac patients.42 and CRP was shown to decrease survival, differentiation and function of endothelial cell precursors43 and to inhibit angiogenesis by suppressing nitric oxide production.44 Although our results clearly associate elevated levels of CRP with the presence of colorectal cancer, more studies are necessary CRP levels can be linked to tumor angiogenesis.

Among the 9 factors investigated we could only find a strong correlation between VEGF-A and MMP-9 levels, most notably in CRC patients (Fig. 3). To our knowledge, this correlation has not been described previously in the blood of patients with solid tumors, but it was seen in pleural effusions in patients with tuberculosis and lung cancer45 and in the plasma of patients with adult T cell leukemia.46 This correlation is consistent with preclinical data reporting functional interdependence between VEGF-A and MMP-9: VEGF-A can induce MMP-9 expression in different cells, whereas MMP-9 can promote the release of ECM- and cell surface-bound VEGF-A, thereby increasing its bioavailability. VEGF-A was reported to enhance production of MMP-9 by human vascular smooth muscle cells47 and to induce MMP-9 in pre-metastatic lung endothelial cells and macrophages, thereby promoting lung metastasis formation.48 In the Rip1Tag2 model of multistep carcinogenesis, increased MMP-9 activity promoted the release of matrix-bound VEGF-A resulting in the angiogenic switch and enhanced tumor progression.49 In ovarian cancer cells MMP-9 activity promoted angiogenesis48 and dose-dependent VEGF-A release.49 A correlation trend was found between increased levels of CRP and VEGF-A, and CRP and MMP-9 (R² = 0.43 and R² = 0.36, respectively) and between IL-8 levels and VEGF-A and MMP-9 (R² = 0.604 and R² = 0.402, respectively).

Although our study was not designed to demonstrate correlations between the measured factors and clinical parameters, some interesting trends between VEGF-A or MMP-9 and clinical-pathological characteristics, were nevertheless observed. In breast cancer, VEGF-A levels tended to be higher in patients with larger tumors, advanced tumor stages and more aggressive histology (higher grade, negative hormone receptor status). For MMP-9, a trend between elevated levels and larger tumor size and more advanced stages was also observed. In colorectal cancer patients, VEGF-A and MMP-9 values tended to be higher in patients with more advanced tumor stages, local infiltration and lymph node metastases. These observations are in line with published studies.

reporting correlations between circulating levels of VEGF-A and tumor stage,\textsuperscript{50,51} disease progression\textsuperscript{2,25} and patient survival\textsuperscript{54-56} in different cancers. Elevated systemic levels of MMP-9 were reported to be associated to tumor infiltration, tumor stage, node metastasis and poorer survival\textsuperscript{17,58} in various cancers.

In comparison to breast and colorectal cancer patients who were treated by curative surgical resection, we included 8 patients with advanced but still local tumors (i.e., limited to a limb) who received regional chemotherapeutic treatment by ILP. ILP allows local administration of high dose chemotheraphy without affecting other organs, leading to a high proportion of complete tumor regressions.\textsuperscript{59} The pattern of the measured factors before therapy in ILP patients was strikingly different compared to BC and CRC patients and is, in part related to the differences in the type, stage and size of the tumors. The systemic changes observed in ILP patients after therapy were nearly the opposite of those seen in surgically treated patients: significant increase in VEGF-A, SCF, sVEGFR-2, MMP-9, sTie-2 and CRP, and decrease in sVEGFR-1 levels. The rise in SCF level, although modest, may reflect an involvement of the bone marrow in mobilizing angiogenic endothelial cell precursors or mast cells.\textsuperscript{15} These changes are consistent with enhanced angiogenesis, whereas changes observed after surgical tumor removal are consistent with decreased angiogenesis. TNF causes a selective and acute vascular damage to the tumor vasculature resulting in increased accumulation of melphalan in the tumor tissue, followed by a vascular collapse, and a massive, long lasting tumor necrosis.\textsuperscript{60} TNF also elicits a systemic inflammatory response, as demonstrated by the increased systemic levels of sTNF-R2, IL-6, CRP and Tenascin-C.\textsuperscript{60,61} The increase in CRP concentration after ILP was confirmed here and its association with IL-8 levels suggests the possibility that a sustained inflammatory reaction may persists in or around the treated tumors. Such a condition would be consistent with the reported upregulation of IL-8 in response to Ras activation, which is a paradigm of a signaling pathway of tissue repair.\textsuperscript{24} One can therefore postulate that sustained inflammation and tissue hypoxia may persist in and around necrotic tissues after ILP, thereby contributing to an 'angiogenic switch' in these patients. If confirmed, this 'angiogenic switch' is likely to have potential clinical implications because it may favor re-growth of angiogenic vessels thereby promoting survival and growth of tumor cells not killed by the treatment. Among the patients analyzed, 5 experienced a loco-regional relapse and one developed distant metastases on both. It was, however, difficult to correlate progression with the degree of increase in the levels of these factors because of the small sample size. Two patients were treated by surgery after ILP (sarcoma) and tumor tissue was analyzed histologically. The patient with the highest degree of increase in VEGF and MMP-9 showed residual viable tumor tissue, whereas the patient who had only minor modifications in the levels of VEGF, MMP-9 had complete histological remission. These 2 observations are consistent with the hypothesis that a putative angiogenic switch may occur in patients with incomplete anti-tumor response and residual tumor tissue persists after ILP. Because of the potential clinical relevance of this observation, we plan to prospectively compare VEGF-A, MMP-9 and sVEGFR-R1 levels in patients with locally advanced sarcoma undergoing surgical tumor removal or ILP, respectively. In parallel we will evaluate the presence of hypoxic regions in and around the tumors by position emission tomography.\textsuperscript{62} If this hypothesis is confirmed, the administration of an anti-angiogenic agent after ILP to suppress reactive angiogenesis may improve outcome.

In conclusion, among all factors measured, only VEGF-A and MMP-9 consistently correlated to each other, elevated CRP levels were associated with tumor burden, whereas sVEGFR-R1 increased after tumor removal in colorectal cancer. Treatment with chemotherapy and TNF induced caused changes consistent with an 'angiogenic switch.' These results warrant a prospective study to compare the effect of surgical tumor removal vs. chemotherapy on some of these markers and to evaluate their prognostic/predictive value. If the 'angiogenic switch' after ILP will be confirmed, we

**Figure 5 - Correlations.** (a) Correlation between pre-treatment levels of VEGF-A and MMP-9 in colorectal cancer patients and (b) in ILP patients (c). Correlation between post-treatment levels of CRP and IL-8 in ILP patients. The correlation coefficient ($R^2$) is given within each individual panel. RC, colorectal cancer; ILP, sarcoma and melanoma patients.
