ABSTRACT

OBJECTIVES In this study, a systematic analysis was conducted of phasic intracoronary pressure and flow velocity in patients with severe aortic stenosis (AS) and coronary artery disease, undergoing transcatheter aortic valve replacement (TAVR), to determine how AS affects: 1) phasic coronary flow; 2) hyperemic coronary flow; and 3) the most common clinically used indices of coronary stenosis severity, instantaneous wave-free ratio and fractional flow reserve.

BACKGROUND A significant proportion of patients with severe aortic stenosis (AS) have concomitant coronary artery disease. The effect of the valve on coronary pressure, flow, and the established invasive clinical indices of stenosis severity have not been studied.

METHODS Twenty-eight patients (30 lesions, 50.0% men, mean age 82.1 ± 6.5 years) with severe AS and coronary artery disease were included. Intracoronary pressure and flow assessments were performed at rest and during hyperemia immediately before and after TAVR.

RESULTS Flow during the wave-free period of diastole did not change post-TAVR (29.78 ± 14.9 cm/s vs. 30.81 ± 19.6 cm/s; p = 0.64). Whole-cycle hyperemic flow increased significantly post-TAVR (33.44 ± 13.4 cm/s pre-TAVR vs. 40.33 ± 17.4 cm/s post-TAVR; p = 0.006); this was secondary to significant increases in systolic hyperemic flow post-TAVR (27.67 ± 12.1 cm/s pre-TAVR vs. 34.15 ± 17.5 cm/s post-TAVR; p = 0.02). Instantaneous wave-free ratio values did not change post-TAVR (0.88 ± 0.09 pre-TAVR vs. 0.88 ± 0.09 post-TAVR; p = 0.73), whereas fractional flow reserve decreased significantly post-TAVR (0.87 ± 0.08 pre-TAVR vs. 0.85 ± 0.09 post-TAVR; p = 0.001).

CONCLUSIONS Systolic and hyperemic coronary flow increased significantly post-TAVR; consequently, hyperemic indices that include systole underestimated coronary stenosis severity in patients with severe AS. Flow during the wave-free period of diastole did not change post-TAVR, suggesting that indices calculated during this period are not vulnerable to the confounding effect of the stenotic aortic valve. ABBREVIATIONS AND ACRONYMS

AS = aortic stenosis

CAD = coronary artery disease

FFR = fractional flow reserve

FFR-flow = whole-cycle hyperemic flow

iFR = instantaneous wave-free ratio

iFR-flow = flow during the wave-free period of diastole

LV = left ventricular

MVR = microvascular resistance

PdPa-flow = whole-cycle resting flow

TAVR = transcatheter aortic valve replacement

A significant proportion of patients with severe aortic stenosis (AS) have concomitant coronary artery disease (CAD) (1,2). Determining the significance of CAD is challenging because traditional noninvasive and invasive indices of ischemia have not been validated in this setting (3). At present the decision to revascularize a coronary lesion in a patient with severe AS is based on angiography (3). This anatomic approach is unlikely to correctly identify those lesions that are truly flow limiting and may therefore lead to inappropriate treatment decisions (4).

Invasive indices of coronary stenosis severity provide more accurate localization of ischemia than noninvasive indices (5). There are several invasive indices of coronary artery stenosis severity. These are measured either during resting or hyperemic conditions and can be further divided into those that use the complete cardiac cycle (Pd/Pa, fractional flow reserve [FFR] [5]) or only a period within diastole (instantaneous wave-free ratio [iFR] [6]).

To validate whether an invasive index is accurate in determining lesion significance, in patients with severe AS, an understanding of how AS affects coronary flow is required. Transcatheter aortic valve replacement (TAVR) permits unique insights into the acute effects of AS on coronary physiology (7) because intracoronary physiology assessment can be made immediately before and after valve insertion, thereby minimizing any potential confounding factors. In this study, we aimed to use the TAVR model to determine how AS affects 1) phasic coronary flow; 2) hyperemic coronary flow; and 3) the most common clinically used indices of coronary stenosis severity, iFR and FFR.

METHODS

PATIENT POPULATION. Twenty-eight consecutive patients (30 lesions) with severe AS planned for TAVR and moderate to severe CAD were included. Recruiting centers were the Hammersmith Hospital, Imperial College NHS Trust (London, United Kingdom) and Skane University Hospital (Lund, Sweden). TAVR was indicated by international guidelines (3), and the treatment decision was made at a heart team meeting. Exclusion criteria were known nonviable myocardium in the area of the corresponding coronary artery being studied, contraindication to the administration of adenosine, inability to consent, and weight more than 200 kg. All participants gave written informed consent, and the study was given full ethical approval (14/SC/1103).

CARDIAC CATHETERIZATION PROTOCOL. Cardiac catheterization and coronary angiography were undertaken via either the transradial or transfemoral route at the operator's discretion, using standard equipment. A guiding catheter was used to intubate the vessel of interest. Heparin (5,000 U) was administered intra-arterially. A dual-pressure and Doppler sensor-equipped 0.014-inch guidewire was used for all physiological assessments (ComboWire, Volcano, San Diego, California). The guidewire signal was normalized in the aorta and then advanced a minimum of 3 vessel diameters distal to the stenosed segment. After an optimal and stable flow velocity signal was obtained, resting pressure and flow measurements were recorded. Hyperemia was then induced using a 150-μg bolus of intracoronary adenosine, and hyperemic measurements were made. At the end of each recording, the pressure sensor was

returned to the catheter tip to ensure that there was no pressure drift. When drift was identified ($\geq$0.01), all measurements were repeated. Left ventricular end-diastolic pressure (LVEDP) was recorded using a pigtail catheter placed in the LV cavity. The entire protocol was repeated immediately following the deployment of the new aortic valve. An example of an invasive pressure and flow trace is shown in **Figure 1**.

TAVR PROCEDURE. All TAVR procedures were undertaken according to standard clinical protocols. All patients were treated under local anesthesia. The valves used were the balloon-expandable Edwards SAPIEN XT or S3 valve (Edwards Lifesciences, Irvine, California), the self-expandable Medtronic CoreValve or Evolut R valve (Medtronic, Minneapolis, Minnesota), or the repositionable Lotus valve (Boston Scientific, Natick, Massachusetts); valve choice was at the operator's discretion.

ANALYSIS OF HEMODYNAMIC DATA. The hemodynamic signals were processed using the associated instrument console (ComboMap, Volcano) and stored for offline analysis. Analog output feeds were taken from the pressure-velocity console and electrocardiograph, fed into a DAQ-Card AI-16E-4 (National Instruments, Austin, Texas), and acquired at 1 kHz with LabVIEW (National Instruments). Data were analyzed offline using a custom software package designed with MATLAB (The MathWorks, Natick, Massachusetts).

Coronary flow velocity (centimeters per second) was measured at baseline and during hyperemia.

Definitions of hemodynamic variables were as follows:

FFR = Pd_h/Pa_h (5)

iFR = Pd_{wfp}/Pa_{wfp} (6)

Flow during the wave-free period of diastole (iFR-flow) = v_{wfp}

Whole-cycle hyperemic flow (FFR-flow) = v_h

Whole-cycle resting flow (PdPa-flow) = v_b

Systolic flow = $v_{systole}$

Hyperemic microvascular resistance (MVR) = Pd_h/v_h (8)

Basal MVR = Pd_b/v_b (8)

iFR resistance = Pd_{wfp}/v_{wfp} (9)

Systolic resistance = $Pd_{systole}/v_{systole}$

Basal stenosis resistance = $\Delta P_b/v_b$ (10)

Hyperemic stenosis resistance = $\Delta P_h/v_h$ (11)

where Pa is mean aortic pressure; Pd is mean intracoronary pressure distal to a stenosis; wfp is the wave-free period of diastole; v_h is mean flow velocity

distal to a stenosis during hyperemia; v_b is mean flow velocity distal to a stenosis at baseline; ΔP_h is Pa $-$ Pd during hyperemia; and ΔP_b is Pa $-$ Pd at baseline.

Phasic analysis was performed to identify pressure and flow characteristics during different periods of the cardiac cycle. The wave-free period was identified using wave-intensity analysis as previously described (12). A custom-written MATLAB algorithm was used to separate systole, diastole, and the wave-free period to facilitate phasic analysis of hemodynamic data. A schematic outlining how this was performed is shown in **Figure 2**.

STATISTICAL ANALYSIS. Continuous variables are presented as mean $\pm$ SD unless otherwise stated. Comparisons before and after TAVR were performed using a Wilcoxon signed rank test. The threshold for statistical significance was set at 0.05.

RESULTS

PATIENT POPULATION AND PROCEDURAL CHARACTERISTICS. Twenty-eight patients (30 lesions, 50.0% men, mean age 82.1 $\pm$ 6.5 years) were included. Baseline clinical characteristics are summarized in **Table 1**. Data regarding quantitative coronary angiography are shown in **Table 2**. The baseline echocardiographic and procedural characteristics are summarized in **Table 3**. Mean peak aortic valve velocity was 407.18 $\pm$ 93.68 cm/s, and mean peak gradient was 70.01 $\pm$ 32/85 mm Hg with a calculated mean aortic valve area of 0.68 $\pm$ 0.22 cm^2 (velocity-time integral method).

FIGURE 2 Outline of the Definitions and Calculations Used for Hemodynamic Parameters Used in the Phasic Analysis
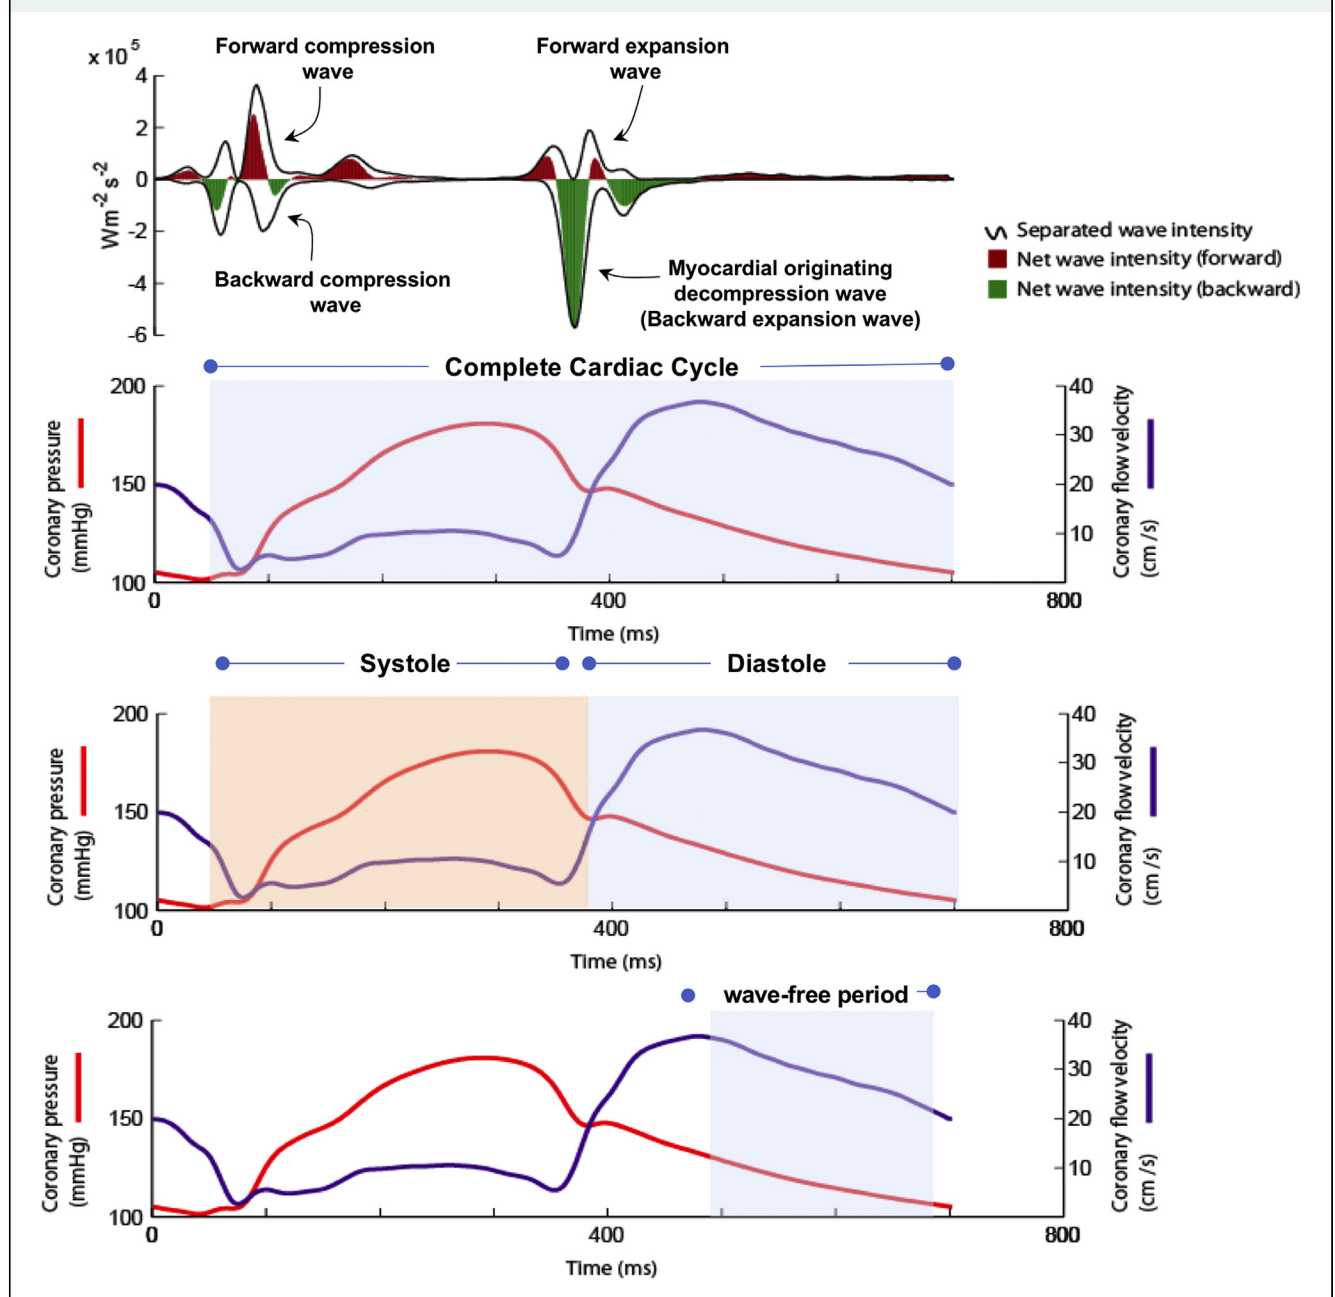

Pre-TAVR, LV systolic function was normal in 20 patients (71.4%), mildly impaired in 3 patients (10.7%), moderately impaired in 2 patients (7.1%), and severely impaired in 3 patients (10.7%). Post-TAVR, LV systolic function was normal in 20 patients (71.4%), mildly impaired in 3 patients (10.7%), moderately impaired in 4 patients (14.3%), and severely impaired in 1 patient (3.6%). Overall there was no significant difference in ejection fraction or heart rate post-TAVR, with a strong trend for

reduction in LV end-diastolic pressure (p = 0.06) (Figure 3, Table 3).

Following TAVR, 15 patients (53.6%) had no paravalvular leak, 13 patients (46.4%) had trivial to mild paravalvular leak, and no patients had mild to moderate, moderate, or severe paravalvular leak (Table 3). **CORONARY FLOW PRE- AND POST-TAVR.** A summary of coronary hemodynamic parameters pre- and post-TAVR, under resting conditions and during hyperemia, is shown in Table 4. An example of

iFR-flow increased by 5.7 ± 3.2%. PdPa-flow changed significantly more than iFR-flow (p = 0.01). FFR-flow also changed significantly more than iFR-flow (p < 0.0001) (**Figure 4**). The change in FFR-flow was similar to the change in PdPa-flow (p = 0.39).

MVR PRE- AND POST-TAVR. Whole-cycle hemodynamic parameters. Whole-cycle resting MVR was unchanged post-TAVR (4.20 ± 1.9 mm Hg · cm · s^{-1} pre-TAVR vs. 4.14 ± 2.1 mm Hg · cm · s^{-1} post-TAVR; p = 0.81). Whole-cycle hyperemic MVR decreased by 7.7% post-TAVR (2.42 ± 0.9 mm Hg · cm · s^{-1} pre-TAVR vs. 2.14 ± 0.9 mm Hg · cm · s^{-1} post-TAVR; p = 0.03).

Systolic hemodynamic parameters. Systolic resting MVR decreased numerically post-TAVR (7.54 ± 3.8 mm Hg · cm · s^{-1} pre-TAVR vs. 6.60 ± 3.5 mm Hg · cm · s^{-1} post-TAVR; p = 0.17). Systolic hyperemic MVR did not change post-TAVR (3.73 ± 1.6 mm Hg · cm · s^{-1} pre-TAVR vs. 3.45 ± 1.6 mm Hg · cm · s^{-1} post-TAVR; p = 0.12).

Wave-free period hemodynamic parameters. Wave-free resting MVR increased by 28.6% post-TAVR (2.59 ± 1.5 mm Hg · cm · s^{-1} pre-TAVR vs. 3.02 ± 1.6 mm Hg · cm · s^{-1} post-TAVR; p = 0.02). Wave-free hyperemic MVR was constant post-TAVR (1.53 ± 0.8 mm Hg · cm · s^{-1} pre-TAVR vs. 1.49 ± 0.6 mm Hg · cm · s^{-1} post-TAVR; p = 0.52).

INDICES OF CORONARY STENOSIS SEVERITY BEFORE AND AFTER TAVR. iFR values did not change post TAVR (0.88 ± 0.09 pre-TAVR vs. 0.88 ± 0.09 post-TAVR; p = 0.94) (**Figure 5**). FFR values significantly decreased after TAVR (0.87 ± 0.08 pre-TAVR vs. 0.85 ± 0.09 post-TAVR; p = 0.0008). Basal

stenosis resistance values did not change post-TAVR (0.31 ± 0.29 pre-TAVR vs. 0.32 ± 0.26 post-TAVR; p = 0.5). Hyperemic stenosis resistance values increased after TAVR (0.34 ± 0.32 pre-TAVR vs. 0.40 ± 0.32 post-TAVR; p = 0.06). A summary of the indices of coronary stenosis severity before and after TAVR is shown in **Table 5**.

DISCUSSION

In this study, we have shown that 1) iFR-flow does not change post-TAVR; 2) FFR-flow increases significantly post-TAVR; 3) changes in FFR-flow are driven by significant increases in systolic flow post-TAVR; and 4) iFR values do no change post-TAVR, whereas FFR decreases significantly post-TAVR.

PHASIC CORONARY FLOW IN PATIENTS WITH SEVERE AS. Coronary flow is phasic and occurs in both systole and diastole. Systolic flow is driven

predominantly by pressure changes at the aortic end of the vessel (13). Diastolic flow is driven by pressure changes at the distal end of the vessel, due to contraction and relaxation of the myocardium and its interaction with the microcirculation (14-16).

During systole, coronary flow is a function of blood emptying from the left ventricle through the aortic valve into the aorta and the opposing compression forces from the contracting myocardium, which blunts systolic flow. In severe AS, systolic coronary flow is reduced because of obstruction of ventricular emptying by the stenosed aortic valve and simultaneous compression of the microcirculation from the contracting myocardium opposing forward flow in the coronary artery, which is augmented by the elevated intraventricular pressure in patients with severe AS (17,18). This results in a reduction in coronary flow during systole. Treatment of the valve stenosis by TAVR removes the mechanical obstruction to ventricular emptying, increases aortic flow, and reduces intraventricular pressure and therefore increases

TAVR = transcatheter aortic valve replacement.

systolic coronary flow (19). This significant systolic increment in flow post-TAVR occurs at rest and during hyperemia (**Figure 6**).
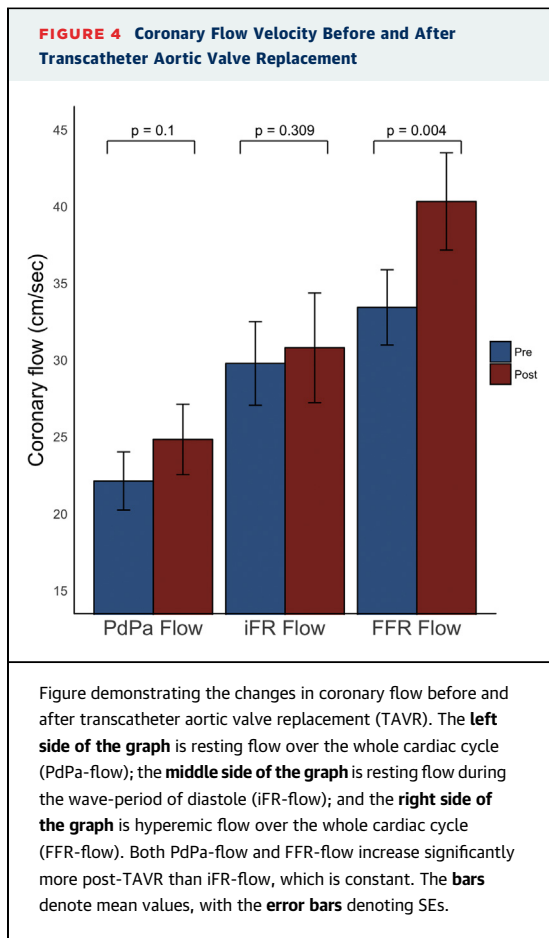

Diastolic flow during the wave-free period occurs when the myocardium is neither contracting nor actively relaxing (12). During this period, the aortic valve is closed. Restriction of aortic valve opening, a systolic phenomenon, therefore does not affect flow during the wave-free period of diastole, because regardless of the severity of AS, the aortic valve leaflets are closed and therefore the aortic valve is not actively contributing to coronary flow.

THE EFFECT OF AORTIC STENOSIS ON HYPEREMIC FLOW. Maximal blood flow in a coronary artery is affected by microvascular structure, function, LV end-diastolic pressure, and right atrial pressure (20-23). Any condition that affects 1 of these determinants will affect maximal flow. In AS, LV afterload is increased because of the stenosed valve (24). This results in raised LV end-diastolic pressure and LV hypertrophy, leading to structural changes in the microcirculation that affect its ability to respond to hyperemic agents (25). Furthermore, patients with severe AS have increased circulating vasoconstrictors as part of a compensatory mechanism to increase vascular tone and maintain systemic blood pressure (26). These vasoconstrictors counteract the effect of administered vasodilators such as adenosine and may therefore also attenuate the response of the coronary microcirculation to adenosine.

The protocol in this study permitted the isolation of the acute effect of treating a stenosed aortic valve on coronary hemodynamics. This study demonstrates that hyperemic flow increases significantly post-TAVR. This is driven by a significant increase in the systolic component of flow. In contrast, flow during the wave-free period does not change during hyperemia post TAVR, which is consistent with the minimal effect of the aortic valve on coronary flow during this period. Therefore, any index of coronary flow that includes the systolic phase of the cardiac cycle will be susceptible to change post-TAVR. In contrast, indices of flow that do not involve systole may be less vulnerable to restriction of aortic valve opening.

INDICES OF CORONARY STENOSIS SEVERITY AND AORTIC STENOSIS. A significant proportion of patients with severe AS also have concomitant CAD (2). The assessment of this disease is challenging, and the established hyperemia-based indices of coronary stenosis severity have not been validated in this setting. Extrapolation of FAME (Fractional Flow Reserve Versus Angiography for Multivessel Evaluation) (4) data would suggest that treatment based on coronary angiography alone is likely to lead to unnecessary revascularization. In addition, coronary intervention is not without risk in patients with severe AS.

The 2 most clinically applicable and validated indices of coronary stenosis severity are FFR and iFR. Although these are both pressure-derived indices of

FIGURE 4 Coronary Flow Velocity Before and After Transcatheter Aortic Valve Replacement

Figure demonstrating the changes in coronary flow before and after transcatheter aortic valve replacement (TAVR). The **left side of the graph** is resting flow over the whole cardiac cycle (PdPa-flow); the **middle side of the graph** is resting flow during the wave-period of diastole (iFR-flow); and the **right side of the graph** is hyperemic flow over the whole cardiac cycle (FFR-flow). Both PdPa-flow and FFR-flow increase significantly more post-TAVR than iFR-flow, which is constant. The **bars** denote mean values, with the **error bars** denoting SEs.

FIGURE 5 Changes in Fractional Flow Reserve and Instantaneous Wave-Free Ratio After Transcatheter Aortic Valve Replacement

Figure demonstrating the change in fractional flow reserve (FFR) and instantaneous wave-free ratio (iFR) values after transcatheter aortic valve replacement. FFR decreases significantly, whereas iFR remains constant. The **bars** denote mean values, with the **error bars** denoting SEs.

stenosis severity, their physiological principles rely on the fact that pressure is proportional to underlying coronary flow during their measurement. Therefore, any change in coronary flow will lead to a change in the pressure-only index.

FFR is measured over the whole cardiac cycle. As a result, it includes systolic flow. The significant change in hyperemic systolic flow immediately after TAVR has a significant effect on whole-cycle flow and therefore FFR. The blunted whole-cycle hyperemic flow pre-TAVR leads to FFR's systematically underestimating coronary stenosis severity in the presence of AS, with an increase in hyperemic flow post-TAVR resulting in FFR values becoming significantly lower across the same coronary stenosis (Figure 7).

iFR is a nonhyperemic index of stenosis severity that is measured during the diastolic wave-free period (6). During this period pressure and flow are proportional. We demonstrate that this diastolic wave-free period exists in patients with severe AS. Furthermore, coronary flow during the diastolic

wave-free period does not change post-TAVR, indicating its relative independence from the acute relief of AS. This ability to discriminate the coronary stenosis severity from AS appears to be true of this period at rest and during hyperemia. The consistency of flow during this period post-TAVR means that, in

Values are mean ± SD.
TAVR = transcatheter aortic valve replacement.

FIGURE 6 Changes in Systolic Coronary Flow After Transcatheter Aortic Valve Replacement

Figure demonstrating the changes in systolic coronary flow after transcatheter aortic valve replacement (TAVR). **(A)** There is a schematic, demonstrating that post-TAVR there is increase in the forward traveling systolic pressure, leading to an increase in systolic coronary flow. There is also a reduction in the compressive forces on the microcirculation post-TAVR; these 2 factors both contribute to a net increase in systolic coronary flow post-TAVR. **(B)** Statistically significantly increase in systolic coronary flow seen in our study, both at rest and during Hyperemia. The **bars** denote mean values, with the **error bars** denoting SEs.

contrast to FFR, the iFR value does not change post-TAVR (**Figure 7**).

These phenomena can also be observed by comparing the results of our study with those of other studies on indices of coronary stenosis severity in patients without severe AS. In the DEFINE-FLAIR (Functional Lesion Assessment of Intermediate Stenosis to Guide Revascularisation) and iFR-SWEDEHEART (Evaluation of iFR vs FFR in Stable Angina or Acute Coronary Syndrome) trials, the mean iFR values were 0.91 ± 0.09 and 0.91 ± 0.10, respectively, similar to the mean iFR of 0.88 ± 0.09 seen in this study. The mean FFR values, however, were 0.83 ± 0.09 in DEFINE-FLAIR and 0.82 ± 0.10 in iFR-SWEDEHEART, lower than those seen in this study (0.87 ± 0.08). This is a function of the

FIGURE 7   Coronary Hemodynamic Status Before and After Transcatheter Aortic Valve Replacement, Over Both the Fractional Flow Reserve and Instantaneous Wave-Free Ratio Measurement Windows

Figure demonstrating the changes in coronary hemodynamic status over the fractional flow reserve (FFR) and instantaneous wave-free ratio (iFR) measurement windows. The **top row** shows the changes in coronary hemodynamics over the FFR window (the whole cardiac cycle during hyperemia): the **left panel** demonstrates a significant increase in flow, the **middle panel** demonstrates a significant reduction in resistance; and as a consequence the **right panel** demonstrates a significant reduction in the FFR value after transcatheter aortic valve replacement (TAVR). The **bottom row** shows the changes in coronary hemodynamic status over the iFR window (the wave-free period of diastole at rest): the **left panel** demonstrates constant flow before and after TAVR; the **right panel** demonstrates a constant iFR value post-TAVR; to achieve the same pressure gradient with the same flow velocity, there is therefore a significant increase in resistance (shown in the **middle panel**). The **bars** denote mean values, with the **error bars** denoting SEs.

attenuated hyperemia in these patients, due to a blunted effect of adenosine resulting in failure to augment flow sufficiently to produce FFR values similar to those in patients without severe AS.

There is a paucity of available data regarding coronary stenosis assessment in patients with severe AS. Existing studies have not measured coronary flow and assumed that it is not affected by

AS (27-29). The present study demonstrates that the effect of adenosine is significantly altered in the presence of AS, and this will consequently significantly affect FFR values and therefore any FFR treatment threshold. The significantly blunted effect of adenosine in these patients suggests that the fundamental intracoronary conditions for accurate FFR assessment cannot be met in patients with severe AS and therefore calls into question the role of FFR as an ischemic standard in these patients (30).

CLINICAL IMPLICATIONS. The findings of this study have potential implications for patients with severe AS and coronary disease who are undergoing TAVR. The ability to isolate coronary stenosis severity in the context of AS will allow clinicians to determine in which patients the valve alone can be treated and which patients need concomitant revascularization, which may be via angioplasty or, in conventional surgical aortic valve replacement, bypass surgery. Hyperemic indices that include systole, such as FFR, are unable to accurately determine coronary stenosis severity in this setting, because of a blunted hyperemic response, suggesting that potentially flow-limiting coronary lesions may be denied appropriate treatment. The degree of AS at which hyperemic flow begins to reduce is also unknown, raising the possibility maximal hyperemia is not achievable in patients with moderate or even mild AS. Furthermore, the variable and unpredictable rate of regression of LV hypertrophy also suggests that FFR may still be vulnerable to an inability to achieve maximal hyperemia for several months after valve treatment.

Flow during the wave-free period of diastole is independent of the severity of the AS, suggesting that iFR can be used to accurately discriminate coronary stenosis severity in the setting of AS. Further studies are required to determine if there is any significant effect of LV hypertrophy regression on iFR values in this setting. The true of role of iFR in patients will be appreciated only with a prospective study comparing an iFR-guided approach to revascularization to standard angiographically guided therapy in patients with severe AS.

STUDY LIMITATIONS. This study included patients with severe symptomatic AS for whom TAVR was decreed the most appropriate therapy by the heart team, in accordance with international guidelines (3). Our results cannot therefore be generalized to patients with more mild degrees of AS.

Adenosine was administered as an intracoronary bolus and not via intravenous infusion. We cannot therefore exclude the possibility that intravenous adenosine infusion would yield different results. However, intracoronary adenosine is recognized as a valid approach to FFR assessment (31,32), and such assessments have been included in all the large randomized trials of physiology to date (33,34). Intravenous infusion was avoided because of the recognized potential for a 15% reduction in aortic pressure (35) that could potentially destabilize a patient with severe AS.

Post-TAVR physiological measurements were made immediately after the valve had been replaced and within the same catheter laboratory procedure. We cannot therefore comment on any more long-term changes in coronary hemodynamics.

The prevalence of severe aortic regurgitation has been significantly reduced with the development of the current generation of TAVR valves (36). This is reflected in the presence of only trivial to mild aortic regurgitation in our dataset compared with other groups that used earlier generation valves (37,38). It is therefore unlikely that the degree of AR, which was mild at most in a minority of our patients, would explain the large differences seen in this study between systolic and diastolic parameters and hyperemia and resting parameters.

The sample size of our study may be considered small, with 30 coronary lesions across 28 patients. However, this is the largest study to date of invasive coronary flow in patients with severe AS and the first to study patients with stenosed coronary arteries. It is also the first study to include phasic analysis, permitting an increase in our understanding of the coronary physiology in this complex hemodynamic condition. This was a mechanistic study, aiming to provide a comprehensive insight to coronary hemodynamic status in patients with severe AS undergoing TAVR. A decision-making strategy for revascularization in patients with severe AS, on the basis of current FFR or iFR data, cannot be made.

This study was designed to compare hyperemic and resting coronary flow and to perform a phasic analysis to delineate differences between systole and diastole. It was not, however, powered to detect differences between resting indices of coronary stenosis severity. Our phasic analysis suggests that there is a significant change in systolic flow post-TAVR, during both resting conditions and hyperemia. This suggests that if the sample

size were increased, we may see significant differences between whole cycle and diastolic resting indices.

CONCLUSIONS

Systolic coronary flow and hyperemic coronary flow are significantly reduced in severe AS and change significantly post-TAVR. Hyperemic indices that include systole therefore provide a limited assessment of true coronary stenosis severity in patients with severe AS. Flow during the wave-free period of diastole does not change post TAVR, suggesting that, in patients with severe AS, coronary indices calculated during this period may be more reflective of true coronary stenosis severity.

PERSPECTIVES

WHAT IS KNOWN? A significant proportion of patients with severe AS have concomitant CAD. There is no established index of coronary stenosis severity in these patients.

WHAT IS NEW? Systolic coronary flow and hyperemic coronary flow are significantly reduced in severe AS and change significantly post-TAVR, making indices of coronary stenosis severity that include systole and are made during hyperemic conditions unreliable in this context. Coronary flow during the wave-free period of diastole does not change post-TAVR, therefore indices restricted to this period are more accurate in patients with severe AS.

WHAT IS NEXT? Prospective randomized trials of coronary revascularization in patients with severe AS are required to determine the optimal method of assessing and treating CAD in this cohort.
